Exercise:
The miracle cure and the role of the doctor in promoting it

February 2015
Foreword

Being active has enormous health and well-being benefits. Physical activity is important in the management of long-term diseases, but, it is even more important in the prevention of many other common diseases. I believe that if physical activity was a drug it would be classed as a wonder drug, which is why I would encourage everyone to get up and be active.

As the population has become more sedentary, conditions such as diabetes and obesity have increased dramatically. The focus of previous reports has been on obesity and nutrition. This report focuses on the less well-known benefits of regular physical activity and the increasing risks of a sedentary lifestyle. Over 40% of adults do not reach the minimum recommended level of 30 minutes of moderately intense exercise five times per week. Evidence in this report highlights that those achieving even this minimum level of activity can reduce their risk of developing heart disease, stroke, dementia, diabetes and some cancers by at least 30%. A society-wide increase in moderate physical activity could help reduce health inequalities and improve mental, as well as physical, health.

Two recent studies neatly illustrate the lack of focus on this issue. The first, by researchers at King's College London\(^1\) showed that 80% of obese patients had never discussed their weight with their GP. The second, by researchers at The University of Cambridge,\(^2\) who conducted a Europe-wide study over 12 years showed that twice as many deaths are due to inactivity than are due to obesity on its own. The Academy has reported on the prime importance of healthy eating.\(^3\)

This report outlines not just ‘why’ doctors in all four nations in the UK must take a leading role in the fight against a sedentary lifestyle, but commendably sets out in clear and simple terms ‘how’ they should do that. I recognise that doctors are frequently prevailed upon to take the lead when it comes to helping people become more active. For me though, this is an integral part of our role in the community. Doctors should lead by example and take every opportunity to provide wise counsel, especially on behalf of those patients who have fewest opportunities in society.

I would like to thank the lead author Scarlett McNally and her colleagues on the Academy's Health Inequalities Forum for their painstaking work in writing this report.

Executive Summary

The big four “proximate” causes of preventable ill-health are: smoking, poor nutrition, lack of physical activity and alcohol excess. Of these, the importance of regular exercise is the least well-known. Relatively low levels of increased activity can make a huge difference. All the evidence suggests small amounts of regular exercise (five times a week for 30 minutes each time for adults) brings dramatic benefits. The exercise should be moderate – enough to get a person slightly out of breath and/or sweaty, and with an increased heart rate. This report is a thorough review of that evidence.

Regular exercise can prevent dementia, type 2 diabetes, some cancers, depression, heart disease and other common serious conditions – reducing the risk of each by at least 30%. This is better than many drugs.

The need to encourage individuals to participate in physical activity has never been greater. Half the population do not reach this level of activity, with wide variations between groups, sufficient to cause ill-health. The costs of physical inactivity to the UK, the NHS and other public bodies are estimated to be in excess of £15bn.

There are greater intangible costs too, to individuals, families and communities. In the UK now, lack of physical activity is acknowledged as one of the top four factors responsible for premature deaths and long-term diseases, and also as a key mechanism for large inequalities in health. These factors (smoking, nutrition, lack of physical activity and alcohol) are often described as lifestyle choices, yet many people do not have the finances, self-efficacy, environment or knowledge to be able to exercise lifestyle “choices”. These are the mechanisms by which inequalities develop. This report is about targeting just one of these factors.

Doctors are increasingly being asked to carry out a range of interventions when they see patients, including screening and changing behaviour, with initiatives such as ‘Make Every Contact Count’. However this report calls on doctors to promote the benefits of regular physical activity to their patients and to communities in their wider roles as ‘advocates for health’. We have some tips, but the message is simple. Exercise is a miracle cure too often overlooked by doctors and the people they care for.

This report sets out what doctors can do on a one-to-one basis and in a broader way with communities and organisations, including their own as many doctors are themselves employers. Helping NHS staff to become more active will help change society. In a wider context, sports and recreational facilities need to actively seek a diversity of clientele, and infrastructure is needed to support more active travel and outdoor spaces. It then sets out a series of case studies which show how relatively simple measures designed to enable and encourage physical activity can make an impact on individuals’ health.

This is about people and their doctors believing that the small effort involved is worth it because they are worth it. This needs to work across the life-course, from children to the very elderly.
Case Study: Prevention is better than cure
Two patients, Jane and Tracy, presented to the same GP in the same week with similar problems.

They were both in their late 40s and worked indoors as office administrators. Both were overweight with moderately high blood pressure and some depression. Both had recent worsening of back pain. The GP suggested to each that they avoid spending long periods sitting and try to be more active.

Angela...

worked in an Ambulance station with a cycle-to-work scheme. She set herself the goal of cycling to work, helped by other colleagues, especially through the dark and rainy times. Within a year Angela had a blood pressure within the normal range and some weight loss. She is now cycling with her son at weekends and has minimal back pain.

Tracy...

did not manage to increase her activity. She had several months off sick with back pain, which worsened with lack of activity. She bought a mobility scooter to save the pain and effort of moving out of a car. Her weight increased and her blood pressure stayed high, requiring medication that she felt made her tired. On one occasion, she fell from the mobility scooter, fracturing her proximal humerus, where the bone had developed osteoporosis from disuse.

This required surgery, then several months of physiotherapy. She was no longer able to work. Routine blood tests three years later revealed type 2 diabetes.
Case Study: Widowers
Two men sadly became widowers in the same week. Both were in their late 60s, and were retired.

Albert...

decided he needed to do more and started attending the local “widows and widowers club” in Bexhill which held dances three times a week. He made friends and kept active over the next few years, requiring no medication and no additional care.

Alan...

thought he should prepare for the future by moving into a flat in sheltered accommodation, rather than staying in the family home. His main pastimes were watching T.V. and driving to the shops. He had increasing blood pressure and felt short of breath whenever he did an unaccustomed activity, such as climbing stairs.

Within 5 years, he was on several different medications for ischaemic heart disease, hypertension, osteoporosis and osteoarthritic pain. He required increasing care from his daughter, who started doing all his shopping, and from the social services team. He tripped over in the flat and sustained a hip fracture, which required major surgery. After the fracture, his daughter suggested that he move into a residential home, where he would be looked after. He died following a stroke a year later.

Although both Albert and Alan thought they were doing the best for their own future, Albert’s active strategy was better for long-term health. Alan’s sedentary lifestyle meant he had a dangerously low level of activity, with a vicious cycle of less activity and worsening health.
Part one: The scale of the problem and the evidence that physical activity improves health in the short and long term
We have moved towards a sedentary society with changing work and domestic habits and patterns. We now drive cars, sit in front of computers or TVs and use domestic appliances. There are far fewer manual jobs. This means that physical activity is not routine for most people. In 1949, 34% of miles travelled using a mechanical mode were by bicycle; today only 1-2% are. Now half of all adults spend more than 5 hours sedentary every day. Fear of traffic and fear of risks outdoors further limit people’s activity.
The link between physical activity and health benefits

Exercise has been called a “wonder drug” or “miracle cure”\(^2\). Increasing physical activity improves health for those with chronic conditions and prevents many common serious medical conditions. The health improvements with physical activity are often greater than many drugs.\(^2,15,16\) The effect is seen with small amounts of physical activity: 30 minutes, 5 times a week. For children 60 minutes per day is the recommended minimum.\(^17\) There are four main physical causes of most preventable ill-health. These “big 4” proximate causes are: poor nutrition, smoking, lack of activity and alcohol. These are also the four main physical causes of most premature deaths and of most inequalities in health. Lack of physical activity is the most recently recognised modifiable risk factor of all the large contributors to ill-health.\(^1,17,18,19\)

Evidence of improvement in health for those with chronic conditions and scale of improvement in the short term (Table 1)

Table 1: Evidence of improvement in health for those with chronic conditions and scale of improvement

<table>
<thead>
<tr>
<th>Condition</th>
<th>Evidence for improvement, and scale of improvement with physical activity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Short term improvements</td>
<td>Many papers report global improvements in health across a range of conditions.(^17) &quot;Physical activity helps to manage over 20 chronic conditions, including coronary heart disease, stroke, type 2 diabetes, cancer, obesity, mental health problems and musculoskeletal conditions&quot;.(^20)</td>
</tr>
<tr>
<td>COPD</td>
<td>Physical activity improves cardiorespiratory health.(^21) Furthermore, in COPD, exercise training reduces dyspnoea symptoms and increases ability for exertion.(^16)</td>
</tr>
<tr>
<td>Heart disease and/or Heart failure and/or Angina</td>
<td>All studies show clear improvements in cardiovascular health with moderate exercise.(^30) There are similar beneficial effects for sufferers of angina.(^27) Overall, exercise reduces cardiac mortality by 31%.(^16)</td>
</tr>
<tr>
<td>Hypertension (high blood pressure)</td>
<td>Hypertension is very common with 10% of adults in England having this diagnosis.(^31) Hypertension is responsible for 50% of strokes and 50% of Ischaemic heart disease.(^28) Most people with hypertension are on long-term medication. Randomised controlled trials show a clear lowering of blood pressure with aerobic training.(^16) The scale of the reduction has been quantified: 31% of patients on average experience a drop of at least 10 mmHg with regular physical activity.(^33)</td>
</tr>
<tr>
<td>Cholesterol</td>
<td>Across several studies, exercise led to a reduction in LDL by an average of 1 to 2mmol/l and an increase in “good” High Density Lipoprotein (HDL).(^16)</td>
</tr>
<tr>
<td>Condition</td>
<td>Description</td>
</tr>
<tr>
<td>-----------------------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td><strong>Obesity</strong></td>
<td>Exercise only has a moderate effect in reducing obesity. Aerobic physical activity has a consistent effect on achieving weight maintenance. Exercise also changes the distribution of fat, by reducing the less healthy visceral [abdominal] fat – for some individuals the body weight may stay the same as muscle is built up but the reduction in visceral fat is highly beneficial for health.</td>
</tr>
<tr>
<td><strong>Depression</strong></td>
<td>There has been a wealth of evidence on the effect of exercise in the treatment of depression, most showing positive outcome. A Cochrane review showed a moderate improvement and in 2009 the Chief Medical Officer’s annual report stated that exercise may be as effective as medication in treatment of depression. NICE guidance on the treatment of depression recommends and gives evidence for the uptake of physical activity as part of a package of other measures. Simple activity has been found to be highly effective for people with mental health issues, eg the ‘walk in to work out’ trial in Glasgow, sustained good results for older people with depression, significant improvements in depression with activity and a 90% improvement in self-esteem and well-being with “citherapy” or any physical activity outdoors. Trials with small numbers of patients do not always detect clear differences in mental health with physical activity. An updated Cochrane review evaluated 30 trials of physical activity as a treatment for depression, showing overall ‘moderate’ improvement.</td>
</tr>
<tr>
<td><strong>Peripheral vascular disease</strong></td>
<td>Exercise leads to a moderate improvement in peripheral vascular disease. Improvements are seen in both pain-free walking time and distance in several studies.</td>
</tr>
<tr>
<td><strong>Diabetes</strong></td>
<td>Exercise has a statistically and clinically significant beneficial effect on glycemic control and the metabolic state. Exercise works as a treatment modality in both type 1 and type 2 diabetes.</td>
</tr>
<tr>
<td><strong>Osteoarthritis</strong></td>
<td>Osteoarthritis is sometimes thought to be related to “wear and tear” yet physical activity improves symptoms of osteoarthritis by 22-83% and does not lead to worsening of this condition. It has benefits in reducing pain (by 25-52%), improving function, improving quality of life and mental health. Others have commented on exercise being weakly effective in osteoarthritis and leading to moderate improvement in low back pain. Exercise increases muscle strength and coordination.</td>
</tr>
<tr>
<td><strong>Chronic pain</strong></td>
<td>Exercise leads to improvement in pain conditions by 25 - 52%.</td>
</tr>
<tr>
<td>Condition</td>
<td>Information</td>
</tr>
<tr>
<td>--------------------</td>
<td>--------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td><strong>Fibromyalgia and fatigue</strong></td>
<td>Aerobic exercise improves physical function and well-being in fibromyalgia. It can also reduce the symptom of fatigue seen in different conditions.</td>
</tr>
<tr>
<td><strong>Cancer</strong></td>
<td>There are few studies looking at exercise as a treatment for cancer, and effects would be expected to vary by type of cancer. In prostate cancer, a 57% lower rate of cancer progression was found with exercise. Exercise helps with side-effects of treatment, improves mood, fatigue and stamina and probably prolongs life.</td>
</tr>
<tr>
<td><strong>Dementia</strong></td>
<td>Physical exercise improves cognitive function and consistently reverses brain atrophy. A significant relationship between physical activity training and improved cognition was obtained for both normal adults and patients with early signs of Alzheimer's disease, in which memory or cognitive ability was mildly impaired. Some studies lament the paucity of case-control studies for exercise in people with established dementia, but all show “strong indications of benefits” in well-being, quality of life, improved balance and strength with reduced falls and more prolonged independence.</td>
</tr>
</tbody>
</table>
It should be noted that these effects occur at low levels of activity – 30 minutes, 5 times per week. The largest health gains occur in people moving from inactive to moderately inactive and from moderately inactive to moderately active. The effects work by different mechanisms. In patients with multiple co-morbidities, physical activity can improve several conditions in different ways. The benefits of physical activity work independently from those of weight change. Increasing ‘fitness’ works in a different way to reducing ‘fatness’ so even people who are overweight can improve their metabolic health by exercising, even if they don’t necessarily lose weight.

**Type 2 Diabetes – the personal costs and the beneficial effect of exercise**

Type 2 diabetes causes problems with sugar processing, metabolism and inflammation. It also causes damage to small blood vessels (microvascular disease), large blood vessels (macrovascular disease) and nerves. There is a greater tendency to infection and a reduced capacity to heal.

Complications are common and affect all systems: diabetic retinopathy (eyesight), nephropathy (kidney failure), neuropathy (nerve damage), microvascular complications, ulcers and sexual dysfunction. Amputations can be needed for infection and poor nerve function in digits or legs. 6,000 foot amputations occur per year in the UK as a result of diabetes.

Individuals with diabetes have a life expectancy that can be shortened by as much as 15 years, with up to 75% dying of macrovascular complications. In England around 1.3 million people currently have a diagnosis of diabetes and the incidence is increasing in all age groups. Around 5% of total NHS resources and up to 10% of hospital inpatient resources are used for the care of people with diabetes. For people with type 2 diabetes, lifestyle interventions are at least as effective as drug treatment. In common with other long-term conditions, the concept of “Number Needed to Treat for Benefit” is helpful in assessing the efficacy of a treatment; in type 2 diabetes, the NNTB is 6.4 for lifestyle interventions compared with 10 for medication, yet medication has more side-effects.

For people without a diagnosis of diabetes, physical activity is proven to reduce the risk of developing type 2 diabetes by 50-80%.
Falls and independence in older people – the beneficial effect of exercise:

Older adults have worrying low levels of activity. Increasing activity could be the key to health improvement by reducing the risk of falls and fractures, by improving or preventing dementia and other long-term conditions and by enabling people to retain their independence. Older adults have the lowest levels of physical activity with only 7% achieving the recommended minimum frequency of five times a week. The requirement for regular physical activity 5 times a week applies equally to older adults, who are often overlooked.

Although older people have the greatest range of health status due to inactivity of any group, they also have the most to gain from increased activity. Exercise is an important means of reducing disability and increasing the number of people living independently.

Being physically active reduces the likelihood of developing dementia and the speed of decline in dementia. Dementia is now the leading cause of death for women in England and Wales.

Approximately 30% of people over 65 years of age living in the community fall each year. 10% (70,000) of ambulance call-outs per year are for older people needing urgent treatment after a fall. 75,000 hip fractures occur per year in the UK, with 95% requiring an operation. 30% of people with a hip fracture die within a year and 50% are dependent for activities of daily living after a hip fracture.

Numerous studies show that exercise programmes are highly effective in older adults and that most will stick to them. Physical activity programmes for older adults that emphasise balance training, coordination and muscle strengthening safely significantly reduce the risk of falls by 30-50%. Exercise also maintains muscle strength and increases bone mineral density so fractures are far less likely even after a fall. Being physically active reduces the risk of later hip fracture by 35-68%.
Evidence of improvement in health for those with chronic conditions and the scale of improvement on the long term

Physical activity comes into its own in the scale of the prevention of future ill-health. There is clear evidence that undertaking physical activity 5 times a week, for 30-minutes each time, can reduce the chance of developing a number of serious and very common conditions.

Table 2: Long term benefits (i.e. preventing diseases) Evidence of reduction in risk of common conditions, and scale of reduction, with exercise at the 30-minutes 5-times-per-week level:

<table>
<thead>
<tr>
<th>Condition</th>
<th>UK lifetime risk of condition</th>
<th>The reduction (% in a person's chance of developing each condition by doing the recommended level of exercise)</th>
<th>Evidence for physical activity preventing certain conditions and the impact (by % of cases prevented)</th>
</tr>
</thead>
<tbody>
<tr>
<td>All-cause mortality (death)</td>
<td>-</td>
<td>30%</td>
<td>Many studies give an approximate 30% risk reduction in all-cause mortality. Smoking is the biggest contributor to early mortality and years living with chronic illness and disability. Physical inactivity, through multiple mechanisms produces an effect one-third the effect of smoking. The World Health Organisation has physical activity as a main plank in its strategy to reduce non-communicable diseases.</td>
</tr>
<tr>
<td>Heart disease</td>
<td>33%</td>
<td>40%</td>
<td>Two-thirds of the burden of cardiovascular diseases can be attributed to the combination of diet and physical inactivity. Physical activity has a very strong effect in reducing the development of heart disease. Studies vary in quantifying the reduction in risk of heart disease as “up to 50%”, or “20 - 35% lower risk” of cardiovascular disease and coronary heart disease. People who change from doing minimal activity to moderate activity have most to gain. Across a population, a move to active travel alone could reduce heart disease by 10%.</td>

* Collated from a number of sources to give a scale of potential future problems – varies according to deprivation.
How much exercise do we typically do?

The minimum recommended amount of physical activity is “5-times-per-week” at moderate intensity for 30 minutes, or 150 minutes per week for adults.12 17 31 The Chief Medical Officers of the 4 nations modified this to include minimising the amount of time spent sedentary (sitting) and recommending 10-minute blocks of varieties of activities. 21 Only 56% of adults in England currently reach this minimum level14 with 62% in Scotland doing so.13

Fewer than a third of adults over age 65 do sufficient exercise.12,85

Health survey Trends, 2008

Twenty seven per cent of UK adults do not even achieve 30 minutes of exercise in total over a week, putting them at a dangerous level of inactivity.15,84

Women report less time doing physical activity than men at all age groups by 10-60%.13,84,86,87

For children, the recommended minimum is 60 minutes moderate intensity exercise per day.17 Girls do significantly less activity than boys.13,88 Depending on methodology, some studies find only 21% of boys and 16% of girls reached the minimum target of one hour per day of exercise,88 whereas others put these figures at 73% of boys and 68% of girls reaching the minimum target.13,89

People in the most deprived socio-economic groups undertake 50% less structured physical activity than those in the least deprived groups.86 The differences in activity levels between groups and within groups mirror the profile of inequalities in health.41 There are wide geographical variations, linked with socio-economic deprivation; for example, the proportion with dangerously sedentary lifestyles, reporting less than 30 minutes activity per week, is 38% in Bradford, West Yorkshire and 17% in Cambridge.84
How is lack of physical activity linked to inequalities in health?

Across the UK there are huge differences in life expectancy and in health between people in different socio-economic groups and between people with different characteristics.90 People in the poorest areas on average spend up to 17 more years living with poor health, die seven years earlier than those in the richest areas91 and are more likely to have several medical conditions.92,93 Recent reports by the British Medical Association94, Department of Health,95 Marmot at the Institute for Health Equity,96 Chief Medical Officers,20 Royal College of Physicians97 and Royal College of General Practitioners,98 have recommended that the medical profession should lead on actions to reduce inequalities in health. Despite decades of such reports, no appreciable change has occurred. There are very few interventions that reduce inequalities in health.95

This is similar to good nutrition, and both lifestyle interventions work synergistically. Despite decades of such reports, no appreciable change has occurred. There are very few interventions that reduce inequalities in health.95 Improving people’s health and wellbeing is a key way to tackle health inequalities.90,100,101,102 The inequalities gap is widening because recent reductions in the four unhealthy behaviours (smoking, alcohol intake, poor nutrition and inactivity) have been greater in more affluent people.4

There is mounting evidence that physical inactivity is a major causative physical link between social inequality and poor health.1,2,3,4,5,6,7,101,103 There is also evidence that tackling physical inactivity should be a major focus to improve health across different groups APCOPA, 2014. There is no other viable intervention which has the potential to improve health in the UK on such a scale. The dose-response graph between amount of physical activity and all-cause mortality is a straight line with a sharp gradient down (Lee and Skerrett 2001). This inverse linear dose-response relationship not only suggests a strong cause and effect relationship between physical inactivity and mortality, but also suggests that even small increases in physical activity can have a life-prolonging (and life-enhancing) effect.

There are barriers stopping people being active, which are different for people from different groups.18,2,1,101,106,107,108 Inequalities in physical activity exist across almost all the nine protected equalities characteristics and across socio-economic groups (PHE, 2014, HM Govt and Mayor of London 2014). People from BME backgrounds are 9% less likely to reach the minimum activity target 10 and 10-25% less likely to be able to swim or cycle.85 Only 11% of Bangladeshi and 14% of Pakistani women were reported to have undertaken the recommended amounts of physical activity, compared with 25% in the general population.3 Similarly, Asian women are far less likely to participate in sports than women of mixed background or white women.106 Unemployed people are 60% less likely to have undertaken physical activity than employed people.85 People with a disability have less than half the activity levels of those without.84,107 Fewer than 20% of people with learning disabilities achieve the minimum target for activity.110 19% of the UK population is classified as having a disability as set out in the Equality Act.45 Only 36% of disabled people reach the minimum activity guidelines (30 minutes, 5 times per week), and 49% do not achieve even 30 minutes of activity per week.

Government policy recommendations include the need to: “target the least active thereby helping to reduce health inequalities – in addition, the health gains for the least active are in relative terms greater than for those who are more physically active.”45
Case Study: Community dancing classes
Beryl is a surgeon working in an urban area. She realised that large numbers of Black and Minority Ethnic (BME) older people in the area were isolated and never exercised and many had heart disease and type 2 diabetes. As Trustee of a not-profit organisation, Beryl helped write a successful bid for funding for a new schedule of dancing classes at the community centre. This enterprise is now thriving, with many people describing the classes as their motivation to get out and be more active. This is an extract from their bid:

“Dancing is a fun and sociable way to obtain 30mins of exercise a day. It is an aerobic exercise if done for more than 10 minutes can strengthen the heart and encourage weight loss. More importantly it can improve muscle strength and balance and reduce mental and physical stress. We also aim for the project to encourage community integration.

We can learn African dancing, Ballroom dancing, Indian dancing, Polish dancing, Turkish dancing etc. from our local community members. We will need to have suitable premises for the regular events, access to music via a laptop and specialist dance teachers for some sessions. We might hold events at weekends to ensure families can participate rather than just retired, unemployed or mothers during the day at weekly events.

We aim to ensure we can assist elderly people, single people, unemployed people and communities that are at high risk of heart disease – Turkish male smokers, Indians with diabetes and Africans with hypertension. We will be able to generate a lot of publicity for our project as it will be unique in bringing together community cohesion by involving different community members of our organisation.”
Economic evidence for focussing on increasing physical activity as a means of improving health and reducing inequalities in health

There are sound economic reasons for encouraging people to be more active, for individuals and for the public purse. Many analyses put the total cost of inactivity in the UK at over £20 billion a year. Costs of inactivity include costs of at least £8bn relating to physical diseases and over £7bn to mental diseases.

The NHS UK budget is £120 billion of which up to 70% is used for care of those with long-term conditions. Financially, measures to support ‘exercise 5-a-week’ could generate savings of at least 15% of the NHS healthcare's £120 billion UK budget and a similar reduction of over 15% in the UK nations’ social care budget. Other bodies have made similar recommendations, including: NICE, BMA, Royal College of Physicians, King's Fund and the Department of Health.

There are additional hidden costs due to reduced productivity. 7% of the working age population is on incapacity benefit, of which 40% is related to mental ill-health and 30% to musculoskeletal conditions or injury. There are further unquantifiable impacts on the children in these families. There are 6 million carers in the UK, most looking after someone with a long-term condition (e.g. dementia, affecting 750,000). Absenteeism (of carers or through sickness) costs the UK in total over 14bn at least £5.5bn of which is related to inactivity.

The largest costs in social care supporting those with long-term conditions: an average Local Authority Residential care place or a complex package of care at home is £50,000 per person per year. 11% of acute hospital inpatient beds are occupied by people with no acute illness, but unable to care for themselves. The numbers of frail older people with multiple medical problems is increasing rapidly yet many conditions are preventable or improved with moderate physical activity.

Changes in infrastructure are needed to increase access places for physical activity and active travel especially for harder to reach groups. The costs of improving the outdoor environment to increase activity are massively outweighed by the benefits. Benefits to costs ratios of between 10:1 and 19:1 are reported for infrastructure to increase walking and cycling, mainly relating to health gains in the local population.
The value of physical exercise to children.  
Dr Jane Ritchie, RCPCH

Physical activity is not just an important contributor to optimal weight; something which applies even to the very young. Exercise is one of the factors which promotes wellbeing and resilience § in childhood, thus improving health behaviours and health outcomes throughout life; resilience being the ability to overcome stressful situations or cope with challenging situations or environments which may have a negative impact on others, despite exposure to situations or insults that create negative effects in others. Evidence suggests that resilience and feeling connected has a positive effect on reducing participation in ‘exploratory’ or risk taking behaviour.134 Compared with other OECD countries, the UK has a higher rate of inequality,134,135 which restricts access for poorer children to creative, sporting or outdoor activities, resulting in a more sedentary and disconnected lifestyle.135

The benefits for children in terms of increased physical and mental health are the same, but there are the additional issues of choice and the life course to consider. Health is more than the result of personal choice and is clearly influenced by the environment in which people are conceived, raised and age. This is particularly the case for children, who do not make choices and learn to adopt the lifestyles to which they have been exposed.136 The life-course perspective, and the idea that disadvantage accumulates throughout life, is central to Marmot Review102 which stresses that the close links between early disadvantage and poor outcomes over time can only be broken by taking action to reduce health inequalities before birth, and throughout the life of the child.134 At the beginning of the life-course, maternal physical and mental health is one of the key drivers of life change throughout childhood, and socio-economic factors such as poverty, unemployment or homelessness may exert their effects on the child by the overall reduction in parental capacity to meet their own, and their children's, emotional and developmental needs.137

Fewer than half of children aged 11 to 15 years engage in at least one hour per day of moderate to vigorous physical activity, and the rate decreases with age. A body of evidence points to the fact that many children are leading a more sedentary life and not experiencing the physical challenges that help them mature and develop resilience,134 and in this respect the accessibility and safety of the built environment is particularly important. Those living in disadvantaged circumstances or poverty, may also experience a lack of parental motivation and initiative, or simple material poverty that does not allow for sports kits, swimming sessions, skate boards or bikes.

This poor level of exercise in children is an important area that should be corrected through intervention and education. Schools, and even early child-care facilities, play an important part, and community initiatives to engage families are ideal. If facilities for exercise or sport are difficult to access or too expensive they will not be used. Investment in open spaces, leisure centres, sports facilities and exercise equipment in parks would help to increase engagement in activity and reduce health problems resulting from a sedentary life. Schools, local authorities, the voluntary sector, those interacting with children and parents need to make sure the right environment is available, ie open spaces and playing fields. One example of an initiative that works to increase exercise is the charity “Living Streets’ Walk to School” campaign, which reaches more than 1.9 million children each year.134 Encouraging adults to be more active will be easier if they have been children who did not become obese, are in the habit of being active and know the benefits to one’s sense of well-being that accrue from regular exercise.
Part two: The role of the doctor in promoting physical activity
Why are doctors the key to encouraging increased physical activity?

Doctors are unique in being trusted, often seeing people at their most vulnerable and interacting with many of those suffering the worst health, in particular those with the most to gain from small improvements in health. Since such a large proportion of the population are inactive or moderately inactive, even small differences in lifestyle may make a big difference to health in the population and encourage behaviour change. Life events can be triggers for change — a health scare, divorce, redundancy etc often create opportunities to re-evaluate. Changing behaviour is very difficult. Messages that work best to ‘trigger’ a change are provocative and come from a trusted source. Doctors already play a central role in evaluating risks and motivating patients with chronic disease. Across all specialties, doctors take safety issues into account on an individual level. We are also are privileged to see people at their most ‘teachable moments’.

By definition, doctors have most interaction with those who are most frequently unwell and hence the people who would have most to gain through regular physical activity. Doctors, especially GPs, have been increasingly expected to monitor and cajole their patients over a number of other measures, recently with the ‘Make Every Contact Count’ initiative. Promoting physical activity may seem an extension of this but is very different. As doctors, we have traditionally focussed on a medical paradigm and the individual patient, yet the scale of improvements in health with physical activity make the promotion of physical activity into the key change to improve health across a very wide range of major and common conditions.

People are often advised to ask their doctor’s advice before embarking on additional exercise. Many doctors doubt their own skills and influence, and feel they lack skills of behavioural advice or doing exercise. Some with a good understanding of health inequalities respond with sympathy, rather than action. Healthcare professionals already possess the required consultation skills to offer advice on increasing physical activity. They often already recognise the underlying behavioural contribution to a presenting condition, and should be reassured that their skills in tackling this are just as effective as “trained” motivational coaches. Follow up is often useful in supporting prolonged behaviour change and is routine for those on “exercise on prescription” schemes.

As well as being in close professional contact with those suffering health inequalities, doctors have influence across the generations, which can work in changing what is considered a normal level of activity.

Doctors are pivotal to encouraging people to increase their levels of activity. “The term ‘brief advice’ is used in this guidance to mean verbal advice, discussion, negotiation or encouragement, with or without written or other support or follow-up. It can vary from basic advice to a more extended, individually focused discussion”; brief advice is very cost effective, especially in older people.
What should doctors be saying to their patients?

The message is simple:

All adults should do physical activity at a minimum amount of 5-times-a-week, for 30 minutes each time. The sessions can be broken into 10- or 15-minute blocks.

The activity should be moderately intense – enough to get a little out of breath and/or to feel your heart rate increase, and/or to feel a little sweaty. For children, a minimum of one hour exercise is expected, five times a week.

Doctors may need to reassure people that the risks of exercise are very low. The risks of sudden death or severe cardiac events during exercise are extremely rare. Even relatively small increases in physical activity are associated with some protection against chronic disease and improved quality of life. Patients need to be advised to stop the activity if they have chest pain, and to slow down if short of breath. People with mechanical problems should avoid jogging or sports with high impact loading, and consider low impact activities such as swimming or cycling. Apart from this, there are surprisingly few restrictions.

The actual activities are not important, as long as they are moderately intense, can be fitted into the person’s schedule and are regular. There is no difference between “structured exercise” and “lifestyle physical activity” in the protective effect offered for the number of minutes of activity. The choice of activity should be relevant, rational and routine. The intensity may need to build up over several sessions. For some, a sociable activity is more likely to be maintained. Young people from deprived backgrounds find group activities, sport and timetabled sessions more attractive when facilities are cheaper and they are given encouragement. Fun activities are more likely to be sustained.

Many activities can be promoted; brisk walking, cycling, climbing stairs, dog-walking, using outdoor gyms and dancing - even sexual activity can bring some benefits. Basing activities in communities leads to sustained acceptance.

For example the Ekta (meaning Unity) project in Newham, East London brings together elderly, isolated, housebound or disabled Asian people and has had great success in increasing activity with regular bhangra dancing classes.
In Hertfordshire the council run Health Walks programme, specifically designed for people who don’t want to or feel they can’t use a gym, has 32,000 participants a year.

Exercises which increase muscle coordination, balance and bone strength reduce falls, osteoporosis and the risk of fractures by 30-50%.50,52,58,148 Dancing has been promoted as part of a “boogie for your bones” campaign.148

People who regularly walk a dog are 34% more likely to attain sufficient weekly physical activity than those who do not.147
The doctor’s role in changing behaviour and changing culture

It is hard to change behaviour. Doctors supporting people to be more physically active need to borrow from coaching techniques, motivational interviewing skills and psychological concepts. This is about embedding the idea that physical activity is good for you. Encouragement, motivation and goal-setting improve long-term changes of behaviour with a physical activity program, especially for older people and women. It is important to be able to advise or refer people on to somewhere, and this is where links with local authority, voluntary sector and private sector schemes can help. People are more likely to act on advice when motivated and when they feel they can get into a programme or the new activity easily.

Changing behaviour requires:

- Knowledge
- Motivation
- Often a trigger
- Easily available opportunities and the skills to be able to change
- The individual to feel empowered or supported, eg by friends
- A physical environment that facilitates the change
- A plan to cope with future potential failure and persevere

The trust a person has in their own ability to change is “self-efficacy” - this can be addressed with motivational interviewing and goal-setting. The “G.R.O.W” model of coaching involves working through:

- Goal (what do I want to achieve?)
- Reality (what is it like now?)
- Options (what might work?)
- What next? (how can I do this and keep doing it?)

The Foresight report on obesity stated that people have difficulty in:

A. Translating intention into action (long-term benefit, forgetfulness, short-term costs).
B. Being aware that Automatic attitudes are different from self-reported attitudes.

Their suggestion was that prior planning and “thinking through” help overcome the risk of failure as people become ‘perceptually ready’ to respond when temptation occurs.
Motivational Interviewing involves similar concepts of engaging, agreeing a focus with the patient, then evoking the patient’s own motivation to change, followed by planning.158,159

- Engaging
- Focusing
- Evoking
- Planning

Doctors should motivate people to stick to their plans and work through perceived and actual barriers, which are different for each individual. Physical inactivity is a lifestyle ‘choice’ yet those with most to gain often have the fewest opportunities to make choices. Doctors can help those who most need this. Regular checks on progress may be helpful and will be more effective if there is integration between primary and secondary care.

It is clear that ‘for most people, the easiest and most acceptable forms of physical activity are those that can be incorporated in everyday life’. It is easiest to fit exercise into a schedule as “active travel”, e.g. walking children to school or cycling to shops.76,160 This is low cost and leads to sustained behaviour change.120,178 The Department of Health’s “change4life” get going programme and NHS “live well” programme both encourage physical activity as part of a healthy lifestyle.161

As well as the individual level, a change in culture is needed so that it is no longer considered “normal” to spend a large amount of time sitting in cars, on sofas and at desks. Furthermore, it needs to become “normal” to do 30-minute sessions of physical activity five times per week. Perseverance with being more physically active is better with community-wide strategies. Changing behaviour needs to come from the individual, but also from their healthcare professionals, friends and family and from the environment. There is ample evidence that increased activity and sustained behavioural change is more successful in a culture that supports it. The risks of ill health from inactivity are very high and outweigh the very low risk of injury from engaging in health promoting activity.162

Ways of changing behaviour and changing culture range on a “ladder of interventions” from guiding choice to legislating.9,163 The Academy’s report71 on obesity suggested ways to ‘make the right choice the easy choice’ by using the ‘nudge effect’.164 Similarly point-of-decision prompts in buildings are effective at encouraging people to use stairs rather than the lift.165 The Lancet suggested a move had occurred “from nudge to nag.”166

The local environment may contain perceived threats (litter, risk of assaults, disturbances from youths) which can deter people, especially the elderly, from walking or cycling in the local area, or letting their children play outside.139 Conversely, improved facilities enable more outdoor activities.159 Doctors need to understand the patient’s environment and work with them to pick regular activities that will be sustainable for them.

Those who are less advantaged may be less likely to take up physical activity, and experience a greater range of barriers, both real and perceived, to integrating physical activity into their daily lives. Interventions to support groups who have fewer resources may need to be designed to reflect specific groups’ living circumstances and may need to be provided in a more intensive and more sustained way.
Putting this into practice – the dos and don’ts of encouraging your patients to exercise

Any conversations on lifestyle should avoid suggesting blame. The scale and importance of physical activity to health has only been acknowledged recently, so past behaviour can be understood without judgement. Doctors should not shy away from these awkward conversations. Activities do not need to be costly and schemes such as ‘cycle-to-work’ schemes through salary sacrifice, or subsidised local recreational sessions may be useful.

Many unhealthy behaviours co-exist, such as smoking, inactivity, alcohol use and poor nutrition. These have a cumulative effect on ill-health, such that all 4 unhealthy behaviours reduces life expectancy by an estimated 14 years. It is possible, and indeed more successful, to tackle several unhealthy behaviours at once.

Doctors giving the clear message that exercise at a minimum level of 30 minutes, 5 times a week, may need to focus on some practical simple steps.

**DO:**

1. Give a clear message the benefits to the person e.g. 'Walking briskly for 30mins a day can reduce your risk of developing dementia because it increases the blood flow to your brain'.

2. Work with the individual to see what form of exercise might work best for them and how to fit this into their schedule, 30 minutes, 5 times per week. Recognise some people may be put off by some types of activity. People with poor self-image are unlikely to want to do gym based exercise.

3. Signpost them to somewhere. Work with your local authority, Health and Wellbeing Board, Public Health bodies, local sports partnership and others to find out what is possible locally. Consider ease of access.

4. Recommend that friends and family help or work together, e.g meeting for a walk as part of “active ageing”. Social networks exert a powerful influence on individual behaviour.

5. Follow up with regular checks at the next clinic, or by phone or text: ‘How’s the exercise going?’

6. Be a role model! Try cycling to work once a week and using the stairs when you can.
DON'T:

1. Don’t be preachy or reprimand.
2. Don’t assume or imply that a patient is lazy
3. Don’t assume they will respond positively immediately – some people take time to consider things.
4. Don’t assume that because you have given information people will act on it
5. Don’t be afraid to suggest a different type of activity next time – the people with most to gain are those who do least.
The practicalities of increasing physical activity

For those unused to physical activity, it is recommended to build up to the level of 30 minutes five times a week over time. The simple message is that the sessions should start gently and build up. The F.I.T.T. principle suggests what can be changed over time to build up the exercise:

- Frequency (times per week) or
- Intensity (how hard) or
- Time (go longer) or
- Type of exercise (eg build up from walk to jog)

There are very few specific instructions for people with different conditions. Most people do not need special advice, as the instructions are simple. For a very small number of those with severe physical problems, a trained exercise therapist may be of benefit, and for others they can be very motivating and inspire cultural change.30,151,167 Those with COPD should be encouraged to wear loose clothing as they may need to rely on diaphragmatic breathing. People with diabetes should exercise more and plan their nutrition around their schedule.168

People may be encouraged to maintain good posture: “Use your “core” muscles: stand tall with your shoulders back, pull in your lower tummy and pelvic floor muscles a little way whenever you are standing or walking.”169

It can be useful to stretch gently before and after a vigorous activity. “When stretching, avoid bouncing as this can cause small muscle tears. Reach for a position and hold it for 5-30 seconds.”169

For some patients, knowledge and confidence can be improved with a leaflet specific to their own medical condition. This may empower them to make the change. For example, very few people know that exercise can improve bone strength and prevent fractures.82 Leaflets are available to help specific groups of people, eg older people170 or those with cardiac problems171 or lung problems172 or osteoporosis.173

The increasing numbers of people using motorised mobility scooters174 need to be aware that their own weekly schedule needs to change to incorporate more times of activity to compensate for their often dangerously low levels of physical activity.

Opportunities are limited by budget and self-efficacy. An 18-hole round of golf involves an average walk of 5 miles, but course fees can keep this exclusive.

Doctors should promote an active lifestyle. Although the benefits of “150 minutes per week” are equivalent to “5 times a week”, there are problems with expecting a sport to fulfil the physical activity requirements; the weather, sporting injury and holidays can reduce the sustainability of sporting activity. Furthermore, there are issues around taking up sport for the first time, and maintaining sporting activity throughout the life course. The Olympic legacy may have left some with continuing sedentary behaviour, if they feel that sport is for spectating and that the Olympic ideal is impossible to achieve.175 It may be easier and better to kick a football around for fun, than to sign up for a football team.159 In addition, for increasing numbers of people, signing up for a future charity challenge is an excellent way of obtaining regular training sessions in the weeks leading up to the event.

The National Obesity forum176 suggests being active is important in preventing and reducing obesity along with tackling “junk food”. Doctors should start having these conversations, although they may be very difficult, as there is often stigma attached.176
It may be helpful for people to realise that there are a finite number of options

Exercise:
The miracle cure and the role of the doctor in promoting it
The doctors’ wider role as employers, leaders in their communities and health ambassadors

Many doctors have wider roles as employers, managers, inspectors or advisors. The NHS is the largest employer in Europe, employing a reported 1.7 million workers across the four nations, as well as being a service provider for all of UK society. The NHS, and other publically-funded bodies, should insist on planning health into the built environment (with access) and into human resource measures, supporting staff. Improved physical activity reduces sickness at work. There are already various opportunities that can help, e.g. workplace wellbeing charter schemes, public health responsibility deal, and Cycle-to-Work schemes with salary sacrifice. Healthcare professionals’ wider role in promoting physical activity should be part of the curriculum at all levels for all clinical staff. Those with oversight of educational programs already have to be assured, and could monitor, that education produces ‘competent and capable staff’.

When commissioning services to prevent or treat conditions such as cardiovascular disease, type 2 diabetes and stroke or to improve mental health, physical activity advice should be incorporated into the care pathway.

Clinicians on Health and Wellbeing boards should be champions for physical activity action at a local government and partnership level. The most gains at community level are in two areas: first, ensuring sport and fitness opportunities appeal to non-traditional participants; second, improving facilities for active travel and green or outdoor spaces. Changes in infrastructure work better than expecting ‘choice’ for harder to reach groups.

Planning that improves safety for those walking and cycling preferentially increases activity of women and older people and has other health gains from reducing pollution and collisions. Doctors are widely respected and interact with all sections of society. They could make useful suggestions locally, since more affluent older people are over-represented in those objecting to planning proposals (eg skate parks which are used by younger people). Targeted facilities for activity in deprived communities have been very successful with sustained uptake. Doctors should support local charities to integrate physical activity messages and activity into what they do.

Exercise has health benefits in addition to any effects on a person’s weight.

**Diagram A**

![Diagram A](image)

**Diagram B**

![Diagram B](image)
Fitness is more important than fatness

Exercise = Fitness

Some reduction in Fatness

Better health

Better glucose metabolism
Reduced stress response
Reduced HDL Cholesterol
  Reduced visceral fat deposition
Better posture Better muscle strength Better bone strength
More resilience to change
Better health
Conclusion

There is overwhelming evidence that physical activity improves the health of people with chronic conditions and also prevents many common diseases, reducing the risk of each of these by 20-50%. It does this at a very achievable amount of 30 minutes of moderate exercise, five times per week. Only 56% of adults achieve this ‘minimum’ weekly target and many people are dangerously inactive. Physical inactivity is responsible for a large proportion of the chronic physical and mental ill-health and is the final physical cause of many inequalities in health. Doctors should encourage individuals to achieve the minimum activity levels. Doctors already have the skills to do this. The messages are simple – start slowly and build up – but, do something. Regular activities need to be fitted into a schedule. Different groups experience different barriers which doctors are well-placed to understand, so the options are different for each person, although there are a finite number of options at each stage of the life course. Although many previous reports have called for action on health inequalities, there has not previously been the clear emphasis on supporting individuals to do more physical activity to improve health on a large scale.

Increased physical activity, particularly getting more people up to the minimum 30 minutes, 5 times a week level, would save over £18bn of NHS costs, saving at least 15% of the NHS budget. As the NHS faces a £30bn funding gap by 2020 the need to tackle preventable illness and disease has never been greater.

This report though, is not simply about saving money, it is about reducing pain and increasing the quality of care. An increase in physical activity at this level would reduce the risk of dementia, stroke and osteoporosis by 30% each which would have a powerful effect on social care costs and reduce the burden on the UK’s 6 million carers.

This intervention is relatively inexpensive and has the potential to improve outcomes for all, not just selected groups. This ‘Miracle cure’ has reducing inequalities in health at its heart.

Doctors should also use their position in society to advocate for changes that will benefit on a wider scale, including harnessing the NHS workforce to help demonstrate and promote more physical activity. In local communities, doctors could advocate for better access to sporting and recreational facilities and changing the environment to enable active travel and activity in outdoor spaces.

In a world of shrinking resources and growing demand, promoting physical activity is the best way to improve the UK nations’ health.
5-a-week physical activity
Part 1

AHIF Health professionals’ guide to 5-a-week

Physical activity + Five times-a-week + 30 minutes can be in 10-minute blocks + Moderately intense increase breathing rate and heart rate + For all Adults* includes elderly and those with disabilities

Why?

Regular exercise is a ‘miracle cure’. Exercise reduces (by 30-80%) your chance of: dementia, type 2 diabetes, heart disease, stroke, depression, breast cancer, heart disease and osteoporosis (weak bones and fractures). Exercise helps manage many diseases too.

Warnings

1. Assess risk
   → High risk (eg severe COPD or severe heart failure) → Refer to professional services
   → Not High risk → Advise start gently and build up

2. Any mechanical problems? (eg recent injury)
   → Advise low impact exercises (gentle walking, swimming or cycling)

3. Safety advice
   → Don’t exercise when you feel hot or unwell
       Stop if you are in pain, feel dizzy, become tired or feel unwell

*For all Adults* includes elderly and those with disabilities.
5-a-week physical activity
Part 2

Practicalities

F.I.T.T: Start gently and build up:
Frequency (times per week) or
Intensity (how hard) or
Time (go longer) or
Type of exercise (eg build up from walk to jog)

Posture: Use your “core” muscles: stand tall with your shoulders back, pull in your lower tummy and pelvic floor muscles a little way whenever you are standing or walking.

Stretch: gently before and after a vigorous activity. When stretching, avoid bouncing as this can cause small muscle tears. Reach for a position and hold it for 5-30 seconds

Suggestions – different for different stages of the life-course:

o TRY brisk walking, dancing, walking the dog, stair climbing, gardening. Avoid sitting!

o TRY to fit it into your schedule: cycle to work/ exercise DVD before your TV program/ walk kids to school/ walk to shops/ family walk rather than family meal, etc

o KEEP MOTIVATED: perhaps exercise with a friend or use a phone exercise app?
